Abstract

We consider a linear regression model with regression parameter $\beta = (\beta_1, \dots, \beta_p)$ and independent and identically $N(0, \sigma^2)$ distributed errors. Suppose that the parameter of interest is $\theta = a^T \beta$ where a is a specified vector. Define the parameter $\tau = c^T \beta - t$ where the vector c and the number t are specified and a and c are linearly independent. Also suppose that we have uncertain prior information that $\tau = 0$. We present a new frequentist $1 - \alpha$ confidence interval for θ that utilizes this prior information. We require this confidence interval to (a) have endpoints that are continuous functions of the data and (b) coincide with the standard $1 - \alpha$ confidence interval when the data strongly contradicts this prior information. This interval is optimal in the sense that it has minimum weighted average expected length where the largest weight is given to this expected length when $\tau = 0$. This minimization leads to an interval that has the following desirable properties. This interval has expected length that (a) is relatively small when the prior information about τ is correct and (b) has a maximum value that is not too large. The following problem will be used to illustrate the application of this new confidence interval. Consider a 2×2 factorial experiment with 20 replicates. Suppose that the parameter of interest θ is a specified *simple* effect and that we have uncertain prior information that the two-factor interaction is zero. Our aim is to find a frequentist 0.95 confidence interval for θ that utilizes this prior information.

1. Introduction

Consider the linear regression model $Y = X\beta + \varepsilon$, where Y is a random n -vector of responses, X is a known $n \times p$ matrix with linearly independent columns, $\beta = (\beta_1, \dots, \beta_p)$ is an unknown parameter vector and $\varepsilon \sim N(0, \sigma^2 I_n)$ where σ^2 is an unknown positive parameter. Suppose that the parameter of interest is $\theta = a^T \beta$ where a is specified p -vector ($a \neq 0$). Define the parameter $\tau = c^T \beta - t$ where the vector c and the number t are specified and a and c are linearly independent. Also suppose that previous experience with similar data sets and/or expert opinion and scientific background suggest that $\tau = 0$. In other words, suppose that we have uncertain prior information that $\tau = 0$. Of course, this includes the particular case that $c = (0, \dots, 0, 1)$ and $t = 0$, so that the uncertain prior information is that $\beta_p = 0$. Our aim is to find a frequentist $1 - \alpha$ confidence interval (i.e. a confidence interval whose coverage probability has infimum $1 - \alpha$) for θ that utilizes this prior information, based on an observation of Y .

An attempt to incorporate the uncertain prior information that $\tau = 0$ into the construction of a $1 - \alpha$ confidence interval for θ is as follows. We carry out a preliminary test of the null hypothesis that $\tau = 0$ against the alternative hypothesis that $\tau \neq 0$. If this null hypothesis is accepted then the confidence interval is constructed assuming that it was known *a priori* that $\tau = 0$; otherwise the standard $1 - \alpha$ confidence interval for θ is used. We call this the naive $1 - \alpha$ confidence interval for θ . This confidence interval is based on a false assumption and so we expect that its minimum coverage probability will not necessarily be $1 - \alpha$. This minimum coverage probability has been investigated by Giri and Kabaila (2008), Kabaila (1998, 2005a), Kabaila and Giri (2009a) and Kabaila and Leeb (2006). In many cases this minimum is far below $1 - \alpha$, showing that this confidence interval is completely inadequate. So, the naive $1 - \alpha$ confidence interval fails to utilize the prior information that $\tau = 0$.

Whilst the naive $1 - \alpha$ confidence interval for θ fails abysmally to utilize the prior information that $\tau = 0$, its form (as described in Section 2) will be used to provide some motivation for the new confidence interval described in Section 3. Similarly to Hodges and Lehmann (1952), Bickel (1983, 1984), Kabaila (1998), Kabaila

(2005b), Farchione and Kabaila (2008), Kabaila and Tuck (2008) and Kabaila and Giri (2009b), our aim is to utilize the uncertain prior information in the frequentist inference of interest, whilst providing a safeguard in case this prior information happens to be incorrect. We assess a $1 - \alpha$ confidence interval for θ using the ratio (expected length of this confidence interval)/(expected length of standard $1 - \alpha$ confidence interval). We call this ratio the scaled expected length of this confidence interval. In Section 3 we describe a new $1 - \alpha$ confidence interval for θ that utilizes the prior information. This interval has endpoints that are continuous functions of the data and it has the following properties. It coincides with the standard $1 - \alpha$ confidence interval when the data strongly contradicts the prior information. This interval is optimal in the sense that it has minimum weighted average expected length where the largest weight is given to this expected length when $\tau = 0$. This minimization leads to an interval that has the following desirable properties. This interval has scaled expected length that (a) is smaller than 1 when the prior information about τ is correct and (b) has a maximum value that is not too much larger than 1. The idea of minimizing a weighted average expected length of a confidence interval, subject to a coverage probability inequality constraint, appears to have been first used by Pratt (1961).

In Section 4 we consider the following scenario. Suppose that a 2×2 factorial experiment, with factors labeled A and B and with more than 1 replicate, has been conducted. Also suppose that our interest is solely in the *simple* effect of changing factor A from low to high when factor B is low. Consider, for example, the case that factor A (B) being low or high corresponds to the absence or presence of treatment A (B), respectively. Our interest may be solely in the effect of treatment A compared to no treatment (cf. Hung et al (1995)). In other words, the parameter of interest θ is the *simple* effect (expected response when factor A is high and factor B is low) – (expected response when factor A is low and factor B is low). In this case, $p = 4$ and we identify τ with the two-factor interaction. Suppose that previous experience with similar data sets and/or expert opinion and scientific background suggest that the two-factor interaction is zero. In a 2×2 factorial clinical trial comparing two drugs whose presumed effects are on completely different systems and/or diseases, it seems

reasonable to suppose that we have uncertain prior information that the two-factor interaction is zero (Stampfer et al (1985), Steering Committee of the Physicians' Health Study Research Group (1988)), Buring and Hennekens (1990) and Hung et al (1995)). For an example of the elicitation of uncertain prior information in a factorial experiment via expert opinion and scientific background in a chemical context see Dubé et al (1996).

An attempt to utilize the uncertain prior information that the two-factor interaction is zero is to use a naive $1 - \alpha$ confidence interval for θ constructed using the following preliminary test. The preliminary test is of the null hypothesis that the two-factor interaction is zero against the alternative hypothesis that the two-factor interaction is non-zero. This confidence interval has a minimum coverage probability that is far below $1 - \alpha$, showing that it is completely inadequate. As an illustration, consider the case that the number of replicates is 20, $1 - \alpha = 0.95$ and the preliminary hypothesis test has level of significance 0.05. We find, using the methodology of Kabaila (1998, 2005a) or Giri and Kabaila (2008) or Kabaila and Giri (2009a), that the minimum coverage probability of this confidence interval is 0.7306. The poor coverage properties of the naive confidence interval are presaged by the poor properties of some other inferences carried out after this preliminary test, see Fabian (1991), Shaffer (1991) and Ng (1994) (cf. Neyman (1935), Bohrer and Sheft (1979) and Traxler (1976)).

The properties of the new confidence interval, described in Section 3, are illustrated in Section 4 by a detailed analysis of the 2×2 factorial experiment example with 20 replicates and $1 - \alpha = 0.95$. Define the parameter $\gamma = \tau / \sqrt{\text{var}(\hat{\tau})}$, where $\hat{\tau}$ denotes the least squares estimator of τ . As proved in Section 3, the coverage probability of the new confidence interval for θ is an even function of γ . The top panel of Figure 3 is a plot of the coverage probability of the new 0.95 confidence interval for θ as a function of γ . This plot shows that the new 0.95 confidence interval for θ has coverage probability 0.95 throughout the parameter space. As proved in Section 3, the scaled expected length of the new confidence interval for θ is an even function of γ . The bottom panel of Figure 3 is a plot of the square of the scaled expected length of the new 0.95 confidence interval for θ as a function of γ . When

the prior information is correct (i.e. $\gamma = 0$), we gain since the square of the scaled expected length is substantially smaller than 1. The maximum value of the square of the scaled expected length is not too large. The new 0.95 confidence interval for θ coincides with the standard $1 - \alpha$ confidence interval when the data strongly contradicts the prior information. This is reflected in Figure 3 by the fact that the square of the scaled expected length approaches 1 as $\gamma \rightarrow \infty$.

2. The naive confidence interval

The naive $1 - \alpha$ confidence interval for θ is constructed as follows. We carry out a preliminary test of the null hypothesis that $\tau = 0$ against the alternative hypothesis that $\tau \neq 0$. If this null hypothesis is accepted then the confidence interval is constructed assuming that it was known *a priori* that $\tau = 0$; otherwise the standard $1 - \alpha$ confidence interval for θ is used. As noted in the introduction, this confidence interval will often have minimum coverage probability far below $1 - \alpha$, showing that it is completely inadequate. In this section we describe the naive confidence interval in a new form that will be used to provide some motivation for the new confidence interval described in the next section.

Let $\hat{\beta}$ denote the least squares estimator of β . Let $\hat{\Theta}$ denote $a^T \hat{\beta}$ i.e. the least squares estimator of θ . Also, let $\hat{\tau}$ denote $c^T \hat{\beta} - t$ i.e. the least squares estimator of τ . Define the matrix V to be the covariance matrix of $(\hat{\Theta}, \hat{\tau})$ divided by σ^2 . Let v_{ij} denote the (i, j) th element of V . The standard $1 - \alpha$ confidence interval for θ is $I = [\hat{\Theta} - t_{n-p, 1-\frac{\alpha}{2}} \sqrt{v_{11}} \hat{\sigma}, \hat{\Theta} + t_{n-p, 1-\frac{\alpha}{2}} \sqrt{v_{11}} \hat{\sigma}]$, where the quantile $t_{m,a}$ is defined by $P(T \leq t_{m,a}) = a$ for $T \sim t_m$ and $\hat{\sigma}^2 = (Y - X\hat{\beta})^T(Y - X\hat{\beta})/(n - p)$.

The naive $1 - \alpha$ confidence interval for θ is obtained as follows. The usual test statistic for testing the null hypothesis that $\tau = 0$ against the alternative hypothesis that $\tau \neq 0$ is $\hat{\tau}/(\hat{\sigma}\sqrt{v_{22}})$. Suppose that, for some given positive number q , we fix τ at 0 if $|\hat{\tau}|/(\hat{\sigma}\sqrt{v_{22}}) \leq q$; otherwise we allow τ to vary freely. We use the notation $[a \pm b]$ for the interval $[a - b, a + b]$ ($b > 0$). Also define $\rho = v_{12}/\sqrt{v_{11}v_{22}}$. Note that ρ is the correlation between $\hat{\Theta}$ and $\hat{\tau}$ and so it satisfies $-1 \leq \rho \leq 1$. The naive $1 - \alpha$ confidence interval is as follows (Kabaila and Giri (2009a)). If $|\hat{\tau}|/(\hat{\sigma}\sqrt{v_{22}}) > q$ then this confidence interval is $[\hat{\Theta} - t_{n-p, 1-\frac{\alpha}{2}} \sqrt{v_{11}} \hat{\sigma}, \hat{\Theta} + t_{n-p, 1-\frac{\alpha}{2}} \sqrt{v_{11}} \hat{\sigma}]$. If, on

the other hand, $|\hat{\tau}|/(\hat{\sigma}\sqrt{v_{22}}) \leq q$ then this confidence interval is

$$\left[\hat{\Theta} - \frac{v_{12}}{v_{22}} \hat{\tau} \pm t_{n-p+1, 1-\frac{\alpha}{2}} \sqrt{\frac{(n-p)\hat{\sigma}^2 + (\hat{\tau}^2/v_{22})}{n-p+1}} \sqrt{v_{11} - \frac{v_{12}^2}{v_{22}}} \right].$$

This confidence interval can be expressed in the new form

$$\left[\hat{\Theta} - \sqrt{v_{11}} \hat{\sigma} b\left(\frac{\hat{\tau}}{\hat{\sigma}\sqrt{v_{22}}}\right) \pm \sqrt{v_{11}} \hat{\sigma} s\left(\frac{|\hat{\tau}|}{\hat{\sigma}\sqrt{v_{22}}}\right) \right]$$

where

$$b(x) = \begin{cases} 0 & \text{for } |x| > q \\ \rho x & \text{for } |x| \leq q. \end{cases}$$

$$s(x) = \begin{cases} t_{n-p, 1-\frac{\alpha}{2}} & \text{for } x > q \\ t_{n-p+1, 1-\frac{\alpha}{2}} \sqrt{1-\rho^2} \sqrt{\frac{n-p+x^2}{n-p+1}} & \text{for } 0 < x \leq q. \end{cases}$$

In Section 4 we will consider the example of a 2×2 factorial experiment with 20 replicates. Here $p = 4$. The parameter of interest θ is the *simple* effect (expected response when factor A is high and factor B is low) – (expected response when factor A is low and factor B is low). We identify τ with the two-factor interaction, so that $\rho = -1/\sqrt{2} = -0.7071068$. Suppose that we have uncertain prior information that the two-factor interaction is zero. Also suppose that we carry out a preliminary test of the null hypothesis that the two-factor interaction is zero against the alternative hypothesis that this interaction is non-zero. Let the level of significance of this test be 0.05, so that $q = 1.991673$. Figure 1 is a plot of the functions b and s for the resulting naive 0.95 confidence interval for θ . This confidence interval is completely inadequate, as its minimum coverage probability is 0.7306. It also has the unpleasant feature that its endpoints are discontinuous functions of the data.

Figure 1: Plots of the functions b and s for the naive 0.95 confidence interval for the *simple* effect θ in the context of the 2×2 factorial experiment with 20 replicates. This confidence interval is based on a preliminary test of the null hypothesis that the two-factor interaction is zero against the alternative hypothesis that this interaction is non-zero, with level of significance 0.05.

3. New confidence interval utilizing prior information

In this section we describe a broad class of confidence intervals for θ . These confidence intervals are required to have endpoints that are smooth function of the data. They are also required to coincide with the standard $1 - \alpha$ confidence intervals when the data strongly contradict the prior information. We provide computationally convenient expressions for the coverage probability and the scaled expected length for confidence intervals from this class. These computationally convenient expressions were first described by Kabaila and Giri (2007a,b). We then describe a weight function for the difference ((scaled expected length of the confidence interval) – (scaled expected length of the standard $1 - \alpha$ confidence interval)). This weight function gives the largest weight to this difference when $\tau = 0$ i.e. when the prior information is correct. We find an interval that is optimal in the sense that it minimizes the weighted average of this difference subject to the constraint that it has minimum coverage probability $1 - \alpha$. Our choice of the weight function ensures that this interval utilizes the prior information.

We introduce a confidence interval for θ that is similar in form to the naive $1 - \alpha$ confidence interval, described in the previous section, but with a great “loosening up” of the forms that the functions b and s can take. Define the following confidence interval for θ

$$J(b, s) = \left[\hat{\Theta} - \sqrt{v_{11}} \hat{\sigma} b\left(\frac{\hat{\tau}}{\hat{\sigma} \sqrt{v_{22}}}\right) \pm \sqrt{v_{11}} \hat{\sigma} s\left(\frac{|\hat{\tau}|}{\hat{\sigma} \sqrt{v_{22}}}\right) \right] \quad (1)$$

where the functions b and s are required to satisfy the following restriction.

Restriction 1

$b : \mathbb{R} \rightarrow \mathbb{R}$ is constrained to be an odd function and $s : [0, \infty) \rightarrow [0, \infty)$.

The motivation for restricting attention to this form of interval is provided by the new invariance arguments presented in Appendix A. We also require that the functions b and s satisfy the following restriction.

Restriction 2

b and s are continuous functions.

This implies that the endpoints of the confidence interval $J(b, s)$ are continuous functions of the data. Finally, we require the confidence interval $J(b, s)$ to coincide

with the standard $1 - \alpha$ confidence interval I when the data strongly contradict the prior information. The statistic $|\hat{\tau}|/(\hat{\sigma}\sqrt{v_{22}})$ provides some indication of how far away $\tau/(\sigma\sqrt{v_{22}})$ is from 0. We therefore require that the functions b and s satisfy the following restriction.

Restriction 3

$b(x) = 0$ for all $|x| \geq d$ and $s(x) = t_{n-p, 1-\frac{\alpha}{2}}$ for all $x \geq d$ where d is a (sufficiently large) specified positive number.

Define $\gamma = \tau/(\sigma\sqrt{v_{22}})$, $G = (\hat{\Theta} - \theta)/(\sigma\sqrt{v_{11}})$ and $H = \hat{\tau}/(\sigma\sqrt{v_{22}})$. Note that

$$\begin{bmatrix} G \\ H \end{bmatrix} \sim N \left(\begin{bmatrix} 0 \\ \gamma \end{bmatrix}, \begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix} \right). \quad (2)$$

where, as defined in Section 2, $\rho = v_{12}/\sqrt{v_{11}v_{22}}$. Also define $W = \hat{\sigma}/\sigma$. Note that (G, H) and W are independent random vectors. Also, W has the same distribution as $\sqrt{Q/(n-p)}$ where $Q \sim \chi_{n-p}^2$. Let f_W denote the probability density function of W .

It is straightforward to show that the coverage probability $P(\theta \in J(b, s))$ is equal to $P(\ell(H, W) \leq G \leq u(H, W))$, where the functions $\ell(\cdot, \cdot) : \mathbb{R} \times [0, \infty) \rightarrow \mathbb{R}$ and $u(\cdot, \cdot) : \mathbb{R} \times [0, \infty) \rightarrow \mathbb{R}$ are defined by $\ell(h, w) = b(h/w)w - s(h/w)w$ and $u(h, w) = b(h/w)w + s(h/w)w$. For given b, s and ρ , the coverage probability of $J(b, s)$ is a function of γ . We denote this coverage probability by $c(\gamma; b, s, \rho)$.

Part of our evaluation of the confidence interval $J(b, s)$ consists of comparing it with the standard $1 - \alpha$ confidence interval I using the criterion

$$\frac{\text{expected length of } J(b, s)}{\text{expected length of } I}. \quad (3)$$

We call this the scaled expected length of $J(b, s)$. This is equal to

$$\frac{E \left(s \left(\frac{|H|}{W} \right) W \right)}{t_{n-p, 1-\frac{\alpha}{2}} E(W)}.$$

This is a function of γ for given s . We denote this function by $e(\gamma; s)$. Clearly, for given s , $e(\gamma; s)$ is an even function of γ .

Our aim is to find functions b and s that satisfy Restrictions 1–3 and such that (a) the minimum of $c(\gamma; b, s, \rho)$ over γ is $1 - \alpha$ and (b)

$$\int_{-\infty}^{\infty} (e(\gamma; s) - 1) d\nu(\gamma) \quad (4)$$

is minimized, where the weight function ν has been chosen to be

$$\nu(x) = \lambda x + \mathcal{H}(x) \quad \text{for all } x \in \mathbb{R}, \quad (5)$$

where λ is a specified nonnegative number and $\mathcal{H}$ is the unit step function defined by $\mathcal{H}(x) = 0$ for $x < 0$ and $\mathcal{H}(x) = 1$ for $x \geq 0$. The larger the value of λ , the smaller the relative weight given to minimizing $e(\gamma; s)$ for $\gamma = 0$, as opposed to minimizing $e(\gamma; s)$ for other values of γ . Similarly to Farchione and Kabaila (2008), who consider a much simpler model, we expect the weight function (5) to lead to a $1 - \alpha$ confidence interval for θ that has expected length that (a) is relatively small when $\tau = 0$ and (b) has maximum value that is not too large.

The following theorem provides new computationally convenient expressions for the coverage probability and scaled expected length of $J(b, s)$.

Theorem 1.

(a) Define the functions $k^\dagger(h, w, \gamma, \rho) = \Psi(-t_{n-p, 1-\frac{\alpha}{2}}w, t_{n-p, 1-\frac{\alpha}{2}}w; \rho(h-\gamma), 1-\rho^2)$ and $k(h, w, \gamma, \rho) = \Psi(\ell(h, w), u(h, w); \rho(h-\gamma), 1-\rho^2)$, where $\Psi(x, y; \mu, v) = P(x \leq Z \leq y)$ for $Z \sim N(\mu, v)$. The coverage probability of $J(b, s)$ is denoted by $c(\gamma; b, s, \rho)$ and is equal to

$$(1 - \alpha) + \int_0^\infty \int_{-d}^d (k(wx, w, \gamma, \rho) - k^\dagger(wx, w, \gamma, \rho)) \phi(wx - \gamma) dx w f_W(w) dw \quad (6)$$

where ϕ denotes the $N(0, 1)$ probability density function. For given b, s and ρ , $c(\gamma; b, s, \rho)$ is an even function of γ .

(b) The scaled expected length of $J(b, s)$ is

$$e(\gamma; s) = 1 + \frac{1}{t_{n-p, 1-\frac{\alpha}{2}} E(W)} \int_0^\infty \int_{-d}^d (s(|x|) - t_{n-p, 1-\frac{\alpha}{2}}) \phi(wx - \gamma) dx w^2 f_W(w) dw. \quad (7)$$

Substituting (7) into (4), we obtain that (4) is equal to

$$\begin{aligned} & \frac{1}{t_{n-p, 1-\frac{\alpha}{2}} E(W)} \int_{-\infty}^\infty \int_0^\infty \int_{-d}^d (s(|x|) - t_{n-p, 1-\frac{\alpha}{2}}) \phi(wx - \gamma) dx w^2 f_W(w) dw d\nu(\gamma) \\ &= \frac{1}{t_{n-p, 1-\frac{\alpha}{2}} E(W)} \int_0^\infty \int_{-d}^d (s(|x|) - t_{n-p, 1-\frac{\alpha}{2}}) \int_{-\infty}^\infty \phi(wx - \gamma) d\nu(\gamma) dx w^2 f_W(w) dw \\ &= \frac{2}{t_{n-p, 1-\frac{\alpha}{2}} E(W)} \int_0^\infty \int_0^d (s(x) - t_{n-p, 1-\frac{\alpha}{2}}) (\lambda + \phi(wx)) dx w^2 f_W(w) dw \end{aligned} \quad (8)$$

For computational feasibility, we specify the following parametric forms for the functions b and s . We require b to be a continuous function and so it is necessary that $b(0) = 0$. Suppose that $x_1, \dots, x_q$ satisfy $0 = x_1 < x_2 < \dots < x_q = d$. Obviously, $b(x_1) = 0$, $b(x_q) = 0$ and $s(x_q) = t_{n-p, 1-\frac{\alpha}{2}}$. The function b is fully specified by the vector $(b(x_2), \dots, b(x_{q-1}))$ as follows. Because b is assumed to be an odd function, we know that $b(-x_i) = -b(x_i)$ for $i = 2, \dots, q$. We specify the value of $b(x)$ for any $x \in [-d, d]$ by cubic spline interpolation for these given function values, subject to the constraint that $b'(-d) = 0$ and $b'(d) = 0$. We fully specify the function s by the vector $(s(x_1), \dots, s(x_{q-1}))$ as follows. The value of $s(x)$ for any $x \in [0, d]$ is specified by cubic spline interpolation for these given function values (without any endpoint conditions on the first derivative of s). We call $x_1, x_2, \dots, x_q$ the knots.

To conclude, the new $1 - \alpha$ confidence interval for θ that utilizes the prior information that $\tau = 0$ is obtained as follows. For a judiciously-chosen set of values of d , λ and knots x_i , we carry out the following computational procedure.

Computational Procedure

Compute the functions b and s , satisfying Restrictions 1–3 and taking the parametric forms described above, such that (a) the minimum over $\gamma \geq 0$ of (6) is $1 - \alpha$ and (b) the criterion (8) is minimized. Plot $e^2(\gamma; s)$, the square of the scaled expected length, as a function of $\gamma \geq 0$.

Based on these plots and the strength of our prior information that $\tau = 0$, we choose appropriate values of d , λ and knots x_i . The confidence interval corresponding to this choice is the new $1 - \alpha$ confidence interval for θ .

Remark 3.1 Suppose that $\lambda > 0$ is fixed. Also suppose that we apply the Computational Procedure without any parametric restrictions of the form described above. The structure of the criterion (4) when ν is given by (5) make it highly plausible that the resulting $1 - \alpha$ confidence interval for θ will have a scaled expected length $e(\gamma; s)$ that converges uniformly in γ to some limiting function as $d \rightarrow \infty$. It is also highly plausible that this limiting function can be found to a very good approximation by applying this Computational Procedure for d sufficiently large and knots x_i sufficiently closely spaced.

4. Application to the analysis of data from a 2×2 factorial experiment

In this section we consider a 2×2 factorial experiment with 20 replicates and parameter of interest θ the *simple* effect (expected response when factor A is high and factor B is low) – (expected response when factor A is low and factor B is low). We suppose that we have uncertain prior information that the two-factor interaction is zero. We use this example to illustrate the properties of the new $1 - \alpha$ confidence interval for θ that utilizes this prior information, when $1 - \alpha = 0.95$. All of the computations presented in this paper were performed with programs written in MATLAB, using the Optimization and Statistics toolboxes.

Let x_1 take the values -1 and 1 when the factor A takes the values low and high respectively. Also let x_2 take the values -1 and 1 when the factor B takes the values low and high respectively. In other words, x_1 and x_2 are the coded values of the factors A and B respectively. The model for this experiment is

$$Y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_{12} x_1 x_2 + \varepsilon \quad (9)$$

where Y is the response, β_0 , β_1 , β_2 and β_{12} are unknown parameters and the ε for different response measurements are independent and identically $N(0, \sigma^2)$ distributed. Thus $\theta = 2(\beta_1 - \beta_{12})$. Let $\hat{\beta}_1$ and $\hat{\beta}_{12}$ denote the least squares estimators of β_1 and β_{12} respectively. The least squares estimator of θ is $\hat{\Theta} = 2(\hat{\beta}_1 - \hat{\beta}_{12})$. Our uncertain prior information is that $\beta_{12} = 0$. Note that

$$\begin{bmatrix} \hat{\Theta} \\ \hat{\beta}_{12} \end{bmatrix} \sim N \left(\begin{bmatrix} \theta \\ \beta_{12} \end{bmatrix}, \frac{\sigma^2}{80} \begin{bmatrix} 8 & -2 \\ -2 & 1 \end{bmatrix} \right).$$

Hence $\rho = -1/\sqrt{2}$.

We followed the Computational Procedure, described at the end of the previous section, with $d = 6$, $\lambda = 0.2$ and evenly-spaced knots x_i at $0, 1, 2, \dots, 6$. The resulting functions b and s , which specify the new 0.95 confidence interval for θ , are plotted in Figure 2. The performance of this confidence interval is shown in Figure 3. This confidence interval has coverage probability 0.95 throughout the parameter space. When the prior information is correct (i.e. $\gamma = 0$), we gain since $e^2(0; s) = 0.8683$. The maximum value of $e^2(\gamma; s)$ is 1.1070. This confidence interval

coincides with the standard $1 - \alpha$ confidence interval for θ when the data strongly contradicts the prior information, so that $e^2(\gamma; s)$ approaches 1 as $\gamma \rightarrow \infty$. It is interesting to note the broad qualitative similarities between the functions plotted in Figures 1 and 2.

These values of $d = 6$, $\lambda = 0.2$ and knots x_i were obtained after a search that we summarize as follows. Consider $d = 6$, evenly-spaced knots x_i at $0, 1, 2, \dots, 6$ and $\lambda = 0.05, 0.2, 0.5$ and 1 . The Computational Procedure was applied for each of these values. As expected from the form of the weight function, for each of these values of λ , $e^2(\gamma; s)$ is minimized at $\gamma = 0$. For a given value of λ , define the ‘expected gain’ to be $(1 - e^2(0; s))$ and the ‘maximum potential loss’ to be $(\max_{\gamma} e^2(\gamma; s) - 1)$. As shown in Table 1, as λ increases (a) the expected gain decreases and (b) the ratio (expected gain)/(maximum potential loss) increases. By choosing $\lambda = 0.2$ we have both a reasonably large expected gain and a reasonably large value of the ratio (expected gain)/(maximum potential loss).

λ	0.05	0.2	0.5	1
expected gain	0.196	0.1317	0.0822	0.043
maximum potential loss	0.2610	0.1070	0.0503	0.0248
(expected gain)/(maximum potential loss)	0.7509	1.2308	1.6341	1.7338

Table 1: Performance of the new 0.95 confidence interval for $d = 6$ and knots x_i at $0, 1, \dots, 6$ when we vary over $\lambda \in \{0.05, 0.2, 0.5, 1\}$.

Now consider $\lambda = 0.2$ and evenly-spaced knots x_i at $0, 1, 2, \dots, d$ where $d = 4, 6, 8$ and 10 . The Computational Procedure was applied for each of these values. There was a marked improvement in performance of the resulting 0.95 confidence interval when d was increased from 4 to 6. However, the improvement in performance of the resulting 0.95 confidence was negligible when d was increased from 6 to 8 and from 6 to 10. This suggests that increasing d beyond 6 will lead to a negligible improvement in performance of the confidence interval.

Finally, consider $d = 6$, $\lambda = 0.2$ and two sets of evenly-spaced knots x_i at $0, 0.6, 1.2, 1.8, \dots, 6$ and $0, 0.5, 1, 1.5, \dots, 6$. The Computational Procedure was applied to both of these sets of knots. The improvements in performance of the result-

ing 0.95 confidence interval (compared to the performance for $d = 6$, $\lambda = 0.2$ and evenly-spaced knots x_i at $0, 1, 2, \dots, 6$) were practically negligible. This suggests that there will be a practically negligible improvement in performance if the spacing between the evenly-spaced knots is reduced to less than 1.

Figure 2: Plots of the functions b and s for the new $1 - \alpha$ confidence interval in the context of a 2×2 factorial experiment with 20 replicates, parameter of interest the *simple* effect $\theta = 2(\beta_1 - \beta_{12})$ and $1 - \alpha = 0.95$. These functions were obtained using $d = 6$, $\lambda = 0.2$ and the knots x_i at $0, 1, 2, \dots, 6$.

Figure 3: Plots of the coverage probability and $e^2(\gamma; s)$, the squared scaled expected length, (as functions of $\gamma = \beta_{12}/\sqrt{\text{var}(\hat{\beta}_{12})}$) of the new 0.95 confidence interval for the *simple* effect $\theta = 2(\beta_1 - \beta_{12})$ for the 2×2 factorial experiment with 20 replicates. These functions were obtained using $d = 6$, $\lambda = 0.2$ and the knots x_i at $0, 1, 2, \dots, 6$.

5. Discussion

Discussion 5.1 Our motivation for the weight function (5) is as follows. Suppose that the only restriction on the functions $b : \mathbb{R} \rightarrow \mathbb{R}$ and $s : [0, \infty) \rightarrow [0, \infty)$ is that b is an odd function. Consider the weight function $\nu = \mathcal{H}$, which corresponds to all of the weight being placed at $\tau = 0$. The minimization of (4), subject to $P(\theta \in J(b, s)) \geq 1 - \alpha$ for all γ , leads to a $1 - \alpha$ confidence interval for θ with the following properties. This interval has the smallest expected length when $\tau = 0$ (i.e. when the prior information is correct) of any $1 - \alpha$ confidence interval for θ . However, this confidence interval has the weakness that its expected length approaches infinity as $|\gamma| \rightarrow \infty$ (Tuck, 2006). Now consider the weight function $\nu = x$, which corresponds to a uniform weight over $\mathbb{R}$. The minimization of (4), subject to $P(\theta \in J(b, s)) \geq 1 - \alpha$ for all γ , leads to the standard $1 - \alpha$ confidence interval I . Finally, consider the weight function (5), which is a mixture of the weight functions $\mathcal{H}$ and x , for fixed $\lambda > 0$. This weight function puts a large amount of weight at $\tau = 0$, consistent with our desire that the confidence interval has relatively small expected length when the prior information is correct. Also, the x component of this weight function leads to a confidence interval whose expected length has a maximum value that is finite. In addition, the structure of the criterion (4) when ν is given by (5) makes it highly plausible that the $1 - \alpha$ confidence interval resulting from the minimization of (4), subject to $P(\theta \in J(b, s)) \geq 1 - \alpha$ for all γ , will have the desirable feature that it approaches the standard $1 - \alpha$ confidence interval I as the data increasingly contradict the prior information. Fortuitously, this property leads to the computational advantage described in Remark 3.1.

Discussion 5.2 The new $1 - \alpha$ confidence interval is computed to satisfy the constraint that its minimum coverage probability is $1 - \alpha$. For the example described in Section 4, it is remarkable that the new $1 - \alpha$ confidence interval has coverage probability *equal* to $1 - \alpha$ throughout the parameter space. The new $1 - \alpha$ confidence interval has been computed for a wide range of values of $1 - \alpha$, λ , ρ , $n - p$ (including the limiting case $n - p \rightarrow \infty$), d and knots x_i . In each case, the new $1 - \alpha$ confidence interval has coverage probability equal to $1 - \alpha$ throughout the parameter space. This provides strong empirical evidence that the new $1 - \alpha$ confidence interval has

the attractive property that its coverage probability is equal to $1 - \alpha$ throughout the parameter space.

Discussion 5.3 The new $1 - \alpha$ confidence interval has been computed for a wide range of values of $1 - \alpha$, λ , ρ , $n - p$ (including the limiting case $n - p \rightarrow \infty$), d and knots x_i . For each of these values of $1 - \alpha$, λ , d and knots x_i , $e^2(0; s)$ (which is the minimum value of $e^2(\gamma; s)$) decreases when $|\rho|$ increases and/or $(n - p)$ decreases.

Discussion 5.4 Consider the particular case that $\rho = 0$. In this case, we expect that any improvement in performance of the new $1 - \alpha$ confidence interval over the standard $1 - \alpha$ confidence interval I can only be due to improved estimation of the parameter σ . Computations show that the new $1 - \alpha$ confidence interval performs well (in terms of utilizing the uncertain prior information) for small $n - p$, when λ is chosen appropriately. However, the new $1 - \alpha$ confidence interval approaches the standard $1 - \alpha$ confidence interval I as $n - p \rightarrow \infty$.

Discussion 5.5 We briefly compare our frequentist approach with a Bayesian approach to the problem stated in the paper. A full discussion will be presented in a separate paper. For simplicity, suppose that σ^2 is known and that

$$\begin{bmatrix} \hat{\Theta} \\ \hat{\tau} \end{bmatrix} \sim N \left(\begin{bmatrix} \theta \\ \tau \end{bmatrix}, \begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix} \right).$$

For the Bayesian approach, suppose that we choose independent prior pdf's for Θ and τ . Also suppose that for this approach (a) Θ has an uniform improper prior pdf and (b) τ has the prior pdf $\xi\delta(\tau) + (1 - \xi)$ where δ denotes the delta function and ξ is a fixed number satisfying $0 \leq \xi \leq 1$. Contrasting features of the new frequentist $1 - \alpha$ confidence interval for θ described in the present paper and the Bayesian $1 - \alpha$ highest probability density (HPD) regions for Θ include the following:

(a) Suppose that the only restriction on the functions $b : \mathbb{R} \rightarrow \mathbb{R}$ and $s : [0, \infty) \rightarrow [0, \infty)$ is that b is an odd function. Consider the weight function $\nu = \mathcal{H}$, which corresponds to all of the weight being placed at $\tau = 0$. The minimization of (4), subject to $P(\theta \in J(b, s)) \geq 1 - \alpha$ for all γ , leads to a $1 - \alpha$ confidence interval with the smallest expected length when $\tau = 0$ of any $1 - \alpha$ confidence interval for θ . There is *no Bayesian analogue* of this confidence interval. If we choose $\xi = 1$ then the Bayesian $1 - \alpha$ HPD region for Θ is equal to the usual $1 - \alpha$ confidence interval

for θ based on the assumption that $\tau = 0$. This confidence interval has coverage probability with infimum 0.

(b) By the appropriate choices of $1 - \alpha$, ξ , ρ , σ and $\hat{\tau}$, one can find Bayesian $1 - \alpha$ HPD regions for Θ that consist of the union of two disjoint intervals. By contrast, the methodology of the present paper always produces a confidence interval.

(c) By the appropriate choices of $1 - \alpha$, ξ where $\xi < 1$, ρ and σ , one can find Bayesian $1 - \alpha$ HPD regions for Θ that have frequentist minimum coverage probabilities far below $1 - \alpha$.

Discussion 5.6 We briefly discuss the computation of the new confidence interval. A full discussion is provided by Giri (2008) and will be presented in a separate paper. Our first step has been to truncate the integrals with respect to w in (6), (7) and (8) and to find upper bounds on the truncation errors. The computational implementation of the constraints that $c(\gamma; b, s, \rho) \geq 1 - \alpha$ for all $\gamma \geq 0$ is as follows. Restriction 3 implies that, for any reasonable choice of the functions b and s , $c(\gamma; b, s, \rho) \rightarrow 1 - \alpha$ as $\gamma \rightarrow \infty$. The constraints implemented in the computer programs are that $c(\gamma; b, s, \rho) \geq 1 - \alpha$ for each $\gamma \in \{0, \Delta, 2\Delta, \dots, M\Delta\}$ where Δ is sufficiently small and M is sufficiently large.

Discussion 5.7 The new $1 - \alpha$ confidence interval for θ is founded on the assumption that the random errors ε_i are independent and identically $N(0, \sigma^2)$ distributed. This confidence interval is based on the least squares estimator $\hat{\Theta}$ of θ and the estimator $\hat{\sigma}$ of σ . Consequently, it will display the same kind of lack of robustness to non-normality of the random errors as the standard $1 - \alpha$ confidence interval I .

Discussion 5.8 We illustrate our method with the following real data set. We extract a 2×2 factorial data set from the 2^3 factorial data set described in Table 7.5 of Box et al (1963) as follows. Define $x_1 = -1$ and $x_1 = 1$ for “Time of addition of HNO_3 ” equal to 2 hours and 7 hours, respectively. Also define $x_2 = -1$ and $x_2 = 1$ for “heel absent” and “heel present”, respectively. The observed responses are the following: $y = 87.2$ for $(x_1, x_2) = (-1, -1)$, $y = 88.4$ for $(x_1, x_2) = (1, -1)$, $y = 86.7$ for $(x_1, x_2) = (-1, 1)$ and $y = 89.2$ for $(x_1, x_2) = (1, 1)$. We use the model (9). The discussion on p.265 of Box et al (1963) implies that there is uncertain

prior information that $\beta_{12} = 0$. The discussion on p.266 of Box et al (1963) implies that there is an estimator $\hat{\sigma}^2$ of σ^2 , obtained from other related experiments, with the property that $\hat{\sigma}^2/\sigma^2 \sim Q/m$ where $Q \sim \chi_m^2$ and m is effectively infinite. The observed value of $\hat{\sigma}$ is 0.8. As in Section 4, define the parameter of interest θ to be the simple effect (expected response when $x_1 = 1$ and $x_2 = -1$) – (expected response when $x_1 = -1$ and $x_2 = -1$), so that $\theta = 2(\beta_1 - \beta_{12})$. Thus

$$\begin{bmatrix} \hat{\Theta} \\ \hat{\beta}_{12} \end{bmatrix} \sim N \left(\begin{bmatrix} \theta \\ \beta_{12} \end{bmatrix}, \sigma^2 \begin{bmatrix} 2 & -1/2 \\ -1/2 & 1/4 \end{bmatrix} \right).$$

The standard 0.95 confidence interval for θ is $[-1.01745, 3.41745]$. We have also computed the new 0.95 confidence interval for θ using $d = 6$, $\lambda = 0.2$ and equally-spaced knots at $0, 6/8, \dots, 6$. This confidence interval is $[-0.81967, 3.26345]$, which is substantially shorter than the standard 0.95 confidence interval.

Discussion 5.9 Denote the usual $1 - \alpha$ confidence interval for θ , based on the assumption that $\tau = 0$, by K . The naive $1 - \alpha$ confidence interval described in Section 2 may be viewed as being obtained via a monotone discontinuous transition, based on the value of the test statistic $|\hat{\tau}|/(\hat{\sigma}\sqrt{v_{22}})$, from the standard $1 - \alpha$ confidence interval I to K . What are the properties of the confidence interval that results from replacing this monotone discontinuous transition by a monotone continuous transition?

For simplicity, consider the case that $n - p$ is large. Define the quantile z_a by $P(Z \leq z_a) = a$ for $Z \sim N(0, 1)$. In this case, $I = [\hat{\Theta} - z_{1-\frac{\alpha}{2}}\sqrt{v_{11}}\hat{\sigma}, \hat{\Theta} + z_{1-\frac{\alpha}{2}}\sqrt{v_{11}}\hat{\sigma}]$ and $K = [\hat{\Theta} - (\hat{\tau}/(\hat{\sigma}\sqrt{v_{22}}))\rho\sqrt{v_{11}}\hat{\sigma} \pm z_{1-\frac{\alpha}{2}}\sqrt{v_{11}}\hat{\sigma}\sqrt{1 - \rho^2}]$. The naive $1 - \alpha$ confidence interval for θ described in Section 2 may be expressed in the following form

$$g\left(\frac{|\hat{\tau}|}{\hat{\sigma}\sqrt{v_{22}}}\right)I + \left(1 - g\left(\frac{|\hat{\tau}|}{\hat{\sigma}\sqrt{v_{22}}}\right)\right)K \quad (10)$$

where $g : [0, \infty) \rightarrow [0, 1]$ is the step function defined by $g(x) = 0$ for all $x \in [0, q]$ and $g(x) = 1$ for all $x > q$.

Now suppose that, instead, g is a continuous increasing function satisfying $g(0) = 0$ and $g(x) \rightarrow 1$ as $x \rightarrow \infty$. What are the properties of the confidence interval (10) in this case? It is straightforward to show that (10) can be expressed in the form (1) with $b(x) = (1 - g(|x|))\rho x$ for all $x \in \mathbb{R}$ and $s(x) =$

$\left(g(x)(1 - \sqrt{1 - \rho^2}) + \sqrt{1 - \rho^2}\right) z_{1-\frac{\alpha}{2}}$ for all $x \geq 0$. In other words, the confidence interval (10) is of the form (1), but with very severe constraints on the functions b and s . In particular, $s(0) = \sqrt{1 - \rho^2} z_{1-\frac{\alpha}{2}}$ and $s(x)$ is a nondecreasing function that converges to $z_{1-\frac{\alpha}{2}}$ as $x \rightarrow \infty$. The new $1 - \alpha$ confidence interval described in Section 3 has been computed for a wide range of values of $\rho > 0$ and in every single case these very severe constraints are far from satisfied by s . So, the confidence interval (10) does not provide a shortcut to finding the new confidence interval described in Section 3. Indeed, the strength of these constraints on the functions b and s implies that any confidence interval of the form (10) will be far inferior to the new confidence interval described in Section 3. The results of Joshi (1969) show that the confidence interval I is admissible, with the consequence that the minimum coverage probability of the confidence interval (10) must be less than $1 - \alpha$.

Appendix A. Invariance arguments

In this appendix we provide a motivation for considering a confidence interval for θ of the form (1) where $b : \mathbb{R} \rightarrow \mathbb{R}$ is constrained to be an odd function and $s : [0, \infty) \rightarrow [0, \infty)$. We provide this motivation through the invariance arguments listed below. Traditional invariance arguments (see e.g. Casella and Berger (2002, section 6.4)) do not include considerations of the available prior information. The novelty in the present appendix is that the invariance arguments need to take proper account of the prior information. Suppose that we have uncertain prior information that $\tau = 0$. Remember that the parameter of interest θ is defined to be $a^T \beta$.

Our first step is to reduce the data to $(\hat{\Theta}, \hat{\tau}, \hat{\sigma})$. Note that $(\hat{\Theta}, \hat{\tau})$ and $\hat{\sigma}$ are independent random vectors with

$$\begin{bmatrix} \hat{\Theta} \\ \hat{\tau} \end{bmatrix} \sim N \left(\begin{bmatrix} \theta \\ \tau \end{bmatrix}, \sigma^2 V \right).$$

and $(n - p)\hat{\sigma}^2/\sigma^2 \sim \chi_{n-p}^2$. Consider a confidence interval

$$[\ell(\hat{\Theta}, \hat{\tau}, \hat{\sigma}), u(\hat{\Theta}, \hat{\tau}, \hat{\sigma})] \tag{A.1}$$

for θ where $\ell : \mathbb{R} \times \mathbb{R} \times [0, \infty) \rightarrow \mathbb{R}$ and $u : \mathbb{R} \times \mathbb{R} \times [0, \infty) \rightarrow \mathbb{R}$.

Invariance Argument 1

The model for the reduced data may be re-expressed

$$\begin{bmatrix} \hat{\Theta}^\dagger \\ \hat{\tau}^\dagger \end{bmatrix} \sim N \left(\begin{bmatrix} \theta^\dagger \\ \tau^\dagger \end{bmatrix}, (\sigma^\dagger)^2 V \right).$$

where $\theta^\dagger = \theta + c$, $\tau^\dagger = \tau$, $\sigma^\dagger = \sigma$, $\hat{\Theta}^\dagger = \hat{\Theta} + c$ and $\hat{\tau}^\dagger = \hat{\tau}$. Also, let $\hat{\sigma}^\dagger = \hat{\sigma}$. Note that $(\hat{\Theta}^\dagger, \hat{\tau}^\dagger)$ and $(\hat{\sigma}^\dagger)^2$ are independent random vectors with $(n-p)(\hat{\sigma}^\dagger)^2/(\sigma^\dagger)^2 \sim \chi_{n-p}^2$. The uncertain prior information may be re-expressed as $\tau^\dagger = 0$.

This re-expressed model and prior information have the same form as the original model and prior information. Thus the confidence interval $[\ell(\hat{\Theta}^\dagger, \hat{\tau}, \sigma), u(\hat{\Theta}^\dagger, \hat{\tau}, \sigma)]$ for $\theta^\dagger$ must lead to a confidence interval for θ that is identical to (A.1). This implies that $\ell(\hat{\Theta}, \hat{\tau}, \hat{\sigma}) = \hat{\Theta} + \tilde{\ell}(\hat{\tau}, \hat{\sigma})$ and $u(\hat{\Theta}, \hat{\tau}, \hat{\sigma}) = \hat{\Theta} + \tilde{u}(\hat{\tau}, \hat{\sigma})$, where $\tilde{\ell} : \mathbb{R} \times [0, \infty) \rightarrow \mathbb{R}$ and $\tilde{u} : \mathbb{R} \times [0, \infty) \rightarrow \mathbb{R}$.

Invariance Argument 2

Let c be a positive number. The model for the reduced data may be re-expressed

$$\begin{bmatrix} \hat{\Theta}^\dagger \\ \hat{\tau}^\dagger \end{bmatrix} \sim N \left(\begin{bmatrix} \theta^\dagger \\ \tau^\dagger \end{bmatrix}, (\sigma^\dagger)^2 V \right).$$

where $\theta^\dagger = c\theta$, $\tau^\dagger = c\tau$, $\sigma^\dagger = c\sigma$, $\hat{\Theta}^\dagger = c\hat{\Theta}$ and $\hat{\tau}^\dagger = c\hat{\tau}$. Also, let $\hat{\sigma}^\dagger = c\hat{\sigma}$. Note that $(\hat{\Theta}^\dagger, \hat{\tau}^\dagger)$ and $(\hat{\sigma}^\dagger)^2$ are independent random vectors with $(n-p)(\hat{\sigma}^\dagger)^2/(\sigma^\dagger)^2 \sim \chi_{n-p}^2$. The uncertain prior information may be re-expressed as $\tau^\dagger = 0$.

This re-expressed model and prior information have the same form as the original model and prior information. Thus the confidence interval $[\hat{\Theta}^\dagger + \tilde{\ell}(\hat{\tau}^\dagger, \hat{\sigma}^\dagger), \hat{\Theta}^\dagger + \tilde{u}(\hat{\tau}^\dagger, \hat{\sigma}^\dagger)]$ for $\theta^\dagger$ must lead to a confidence interval for θ that is identical to $[\hat{\Theta} + \tilde{\ell}(\hat{\tau}, \hat{\sigma}), \hat{\Theta} + \tilde{u}(\hat{\tau}, \hat{\sigma})]$ for θ . This implies that $\ell(\hat{\Theta}, \hat{\tau}, \hat{\sigma}) = \hat{\Theta} - \tilde{b}(\hat{\tau}/\hat{\sigma})\hat{\sigma} - \tilde{s}(\hat{\tau}/\hat{\sigma})\hat{\sigma}$ and $u(\hat{\Theta}, \hat{\tau}, \hat{\sigma}) = \hat{\Theta} - \tilde{b}(\hat{\tau}/\hat{\sigma})\hat{\sigma} + \tilde{s}(\hat{\tau}/\hat{\sigma})\hat{\sigma}$, where $\tilde{b} : \mathbb{R} \rightarrow \mathbb{R}$ and $\tilde{s} : \mathbb{R} \rightarrow [0, \infty)$.

Invariance Argument 3

The model for the reduced data may be re-expressed

$$\begin{bmatrix} \hat{\Theta}^\dagger \\ \hat{\tau}^\dagger \end{bmatrix} \sim N \left(\begin{bmatrix} \theta^\dagger \\ \tau^\dagger \end{bmatrix}, (\sigma^\dagger)^2 V \right).$$

where $\theta^\dagger = -\theta$, $\tau^\dagger = -\tau$, $\sigma^\dagger = \sigma$, $\hat{\Theta}^\dagger = -\hat{\Theta}$ and $\hat{\tau}^\dagger = -\hat{\tau}$. Also, let $\hat{\sigma}^\dagger = \hat{\sigma}$. Note that $(\hat{\Theta}^\dagger, \hat{\tau}^\dagger)$ and $(\hat{\sigma}^\dagger)^2$ are independent random vectors with $(n-p)(\hat{\sigma}^\dagger)^2/(\sigma^\dagger)^2 \sim \chi_{n-p}^2$. The uncertain prior information may be re-expressed as $\tau^\dagger = 0$.

This re-expressed model and prior information have the same form as the original model and prior information. Thus the confidence interval

$$\left[\hat{\Theta}^\dagger - \tilde{b} \left(\frac{\hat{\tau}^\dagger}{\hat{\sigma}^\dagger} \right) \hat{\sigma}^\dagger - \tilde{s} \left(\frac{\hat{\tau}^\dagger}{\hat{\sigma}^\dagger} \right) \hat{\sigma}^\dagger, \hat{\Theta}^\dagger - \tilde{b} \left(\frac{\hat{\tau}^\dagger}{\hat{\sigma}^\dagger} \right) \hat{\sigma}^\dagger + \tilde{s} \left(\frac{\hat{\tau}^\dagger}{\hat{\sigma}^\dagger} \right) \hat{\sigma}^\dagger \right]$$

for $\theta^\dagger$ must lead to a confidence interval for θ that is identical to the confidence interval

$$\left[\hat{\Theta} - \tilde{b} \left(\frac{\hat{\tau}}{\hat{\sigma}} \right) \hat{\sigma} - \tilde{s} \left(\frac{|\hat{\tau}|}{\hat{\sigma}} \right) \hat{\sigma}, \hat{\Theta} - \tilde{b} \left(\frac{\hat{\tau}}{\hat{\sigma}} \right) \hat{\sigma} + \tilde{s} \left(\frac{|\hat{\tau}|}{\hat{\sigma}} \right) \hat{\sigma} \right]$$

for θ . This implies that $\tilde{b}$ is an odd function and $\tilde{s} : [0, \infty) \rightarrow [0, \infty)$.

Now define the functions $b(x) = (1/\sqrt{v_{11}}) \tilde{b}(\sqrt{v_{22}}x)$ for all $x \in \mathbb{R}$ and $s(x) = (1/\sqrt{v_{11}}) \tilde{s}(\sqrt{v_{22}}x)$ for all $x \geq 0$. Since $\tilde{b}$ is constrained to be an odd function, b is also an odd function. Also, since $\tilde{s} : [0, \infty) \rightarrow [0, \infty)$, $s : [0, \infty) \rightarrow [0, \infty)$. The confidence interval (A.1) is therefore equal to $J(b, s)$ where $b : \mathbb{R} \rightarrow \mathbb{R}$ is an odd function and $s : [0, \infty) \rightarrow [0, \infty)$.

Appendix B. Proof of Theorem 1

Proof of part (a).

The random vectors (G, H) and W are independent. It follows from (2) that the probability density function of H , evaluated at h , is $\phi(h - \gamma)$. Thus

$$c(\gamma; b, s, \rho) = \int_0^\infty \int_{-\infty}^\infty \int_{\ell(h,w)}^{u(h,w)} f_{G|H}(g|h) dg \phi(h - \gamma) dh f_W(w) dw \quad (\text{B.1})$$

where f_W denotes the probability density function of W and $f_{G|H}(g|h)$ denotes the probability density function of G conditional on $H = h$, evaluated at g . The probability distribution of G conditional on $H = h$ is $N(\rho(h - \gamma), 1 - \rho^2)$. Thus the right hand side of (B.1) is equal to

$$\int_0^\infty \int_{-\infty}^\infty k(h, w, \gamma, \rho) \phi(h - \gamma) dh f_W(w) dw \quad (\text{B.2})$$

The standard $1 - \alpha$ confidence interval I has coverage probability $1 - \alpha$. Hence

$$1 - \alpha = \int_0^\infty \int_{-\infty}^\infty k^\dagger(h, w, \gamma, \rho) \phi(h - \gamma) dh f_W(w) dw. \quad (\text{B.3})$$

Subtracting (B.3) from (B.2) and noting that $b(x) = 0$ for all $|x| \geq d$ and $s(x) = t_{n-p, 1-\frac{\alpha}{2}}$ for all $x \geq d$, we find that

$$c(\gamma; b, s, \rho) = (1 - \alpha) + \int_0^\infty \int_{-dw}^{dw} (k(h, w, \gamma, \rho) - k^\dagger(h, w, \gamma, \rho)) \phi(h - \gamma) dh f_W(w) dw.$$

Changing the variable of integration from h to $x = h/w$ in the inner integral, we obtain (6). Using the fact that

$$\begin{bmatrix} -G \\ -H \end{bmatrix} \sim N \left(\begin{bmatrix} 0 \\ -\gamma \end{bmatrix}, \begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix} \right),$$

it may be shown that $P(\theta \in J(b, s))$ is an even function of γ .

Proof of part (b).

The random variables H and W are independent. It follows from (2) that the probability density function of H , evaluated at h , is $\phi(h - \gamma)$. Thus

$$e(\gamma; s) = \frac{1}{t_{n-p, 1-\frac{\alpha}{2}} E(W)} \int_0^\infty \int_{-\infty}^\infty s \left(\frac{|h|}{w} \right) \phi(h - \gamma) dh w f_W(w) dw \quad (\text{B.4})$$

where f_W denotes the probability density function of W . Obviously,

$$1 = \frac{1}{t_{n-p, 1-\frac{\alpha}{2}} E(W)} \int_0^\infty \int_{-\infty}^\infty t_{n-p, 1-\frac{\alpha}{2}} \phi(h - \gamma) dh w f_W(w) dw. \quad (\text{B.5})$$

Note that $s(x) = t_{n-p, 1-\frac{\alpha}{2}}$ for all $x \geq d$. Subtracting (B.5) from (B.4) we therefore obtain

$$e(\gamma; s) = 1 + \frac{1}{t_{n-p, 1-\frac{\alpha}{2}} E(W)} \int_0^\infty \int_{-dw}^{dw} \left(s \left(\frac{|h|}{w} \right) - t_{n-p, 1-\frac{\alpha}{2}} \right) \phi(h - \gamma) dh w f_W(w) dw.$$

Changing the variable of integration in the inner integral from h to $x = h/w$, we obtain (7).
